Nutritive Value of Tree Leaves in the Kansas Flint Hills

J.R. FORWOOD AND C.E. OWENSBY

Abstract
Leaves from bur oak (Quercus macrocarpa Michx.), a bur oak hybrid (bur oak), red elm (Ulmus rubra Muhl.), Osage orange (Maclura pomifera (Raf.) Schneid.), and cottonwood (Populus deltoides Marsh.) were analyzed for crude protein, in vitro dry matter digestibility (IVDMD), and tannic acid equivalents (TAE) from mid September through late October during 1979 and 1980. Samples were taken biweekly from the trees and from the ground after leaf fall. Cottonwood was significantly lower over the season in crude protein than all other species except bur oak. Crude protein content declined with advancing season in all species although not significantly. Leaves on the trees were considerably higher in crude protein than True Prairie understory vegetation or leaves on the ground although leaves on the ground had equal or greater crude protein levels than True Prairie understory vegetation. Sample date and species significantly affected digestibility. Digestibility generally increased during middle sample periods and returned to initial levels in late October. Averages over all dates showed digestibility of Osage orange > cottonwood > red elm > bur oak > cottonwood leaves on the ground were more digestible than those on the ground. Red elm, Osage orange and cottonwood leaves on the tree were more digestible than True Prairie understory vegetation. Osage orange and cottonwood leaves on the ground were more digestible than True Prairie understory vegetation. Tannic acid equivalents of bur oak = bur oak > red elm and cottonwood > Osage orange. Tannic acid equivalents generally increased during the middle sample periods and returned to initial levels in late October. There were no TAE differences between leaves on the trees and those on the ground. Overall quality ranking based on the constituents measured showed Osage orange and red elm to be the highest quality leaves of the group. On the basis of these limited tests, Osage orange and red elm would provide the best roughage source in times of severe drought or as a roughage substitute in cattle finishing rations.

Tree products such as aspen sawdust (Mellenberger et al. 1971), aspen bark silage (Hanke et al. 1978), oak sawdust (El-Sabban et al. 1971), and poplar bark (Enzeman et al. 1968) have been investigated as ruminal feed sources. Methods of determining and modifying their digestibility have also been studied (Mellenberger et al. 1969, Millet et al. 1970). The use of tree products for rumen feed has been focused on residues probably because industry and researchers are concerned with finding a use for the waste and a cheap roughage source at the same time.

Leaves might also be considered a tree residue. In True Prairie areas such as the Kansas Flint Hills, the tons of tree leaves that fall to the ground each autumn are largely ignored by producers as a ruminant roughage source.

We have observed cattle grazing Flint Hills rangeland in the fall selecting tree leaves from the ground almost to the exclusion of the herbaceous or understory vegetation traditionally thought of as ruminant forage. Esophageal samples from steers at these times are noted to be composed largely of tree leaves. Past studies indicate that some tree leaves are nutritionally desirable for their crude protein (Bissell and Strong 1955, Hagan 1953, Oldemeyer et al. 1977, McHargue and Roy 1932, McLeod 1973, Sampson and Samisch 1935, Tarrant 1950, Tew 1970), digestibility (Bissell and Weir 1957, Joshi and Ludri 1966, McLeod 1973, Mia et al. 1960, Oldemeyer et al. 1977, Sampson and Samisch 1935, Wilson 1977), and intake (Joshi and Ludri 1966, Mia et al. 1960, Wilson 1977).

In an effort to explain livestock preference for tree leaves and to compare leaf quality of different trees, we determined crude protein, in vitro dry matter digestibility, and tannic acid equivalents of tree leaves commonly found in the Flint Hills area.

Study Site and Methods
The study area is near Manhattan on the Kansas State University pastures in the northern Flint Hills. Botanical analysis shows the area to be typical True Prairie with big bluestem (Andropogon gerardi Vitman) and indiangrass (Sorghastrum nutans (L.) Nash) comprising over 50% of the total vegetation. Numerous other warm-season grasses, forbs, and woody species constitute the remainder. Groves of deciduous trees fill the loamy lowlands between the hills.

Leaf samples were collected from bur oak (Quercus macrocarpa Michx.), red elm (Ulmus rubra Muhl.), Osage orange (Maclura pomifera (Raf.) Schneid.), and cottonwood (Populus deltoides Marsh.) at biweekly intervals from mid September to late October in 1979 and 1980. Samples were also collected from trees originally thought to be white oak (Quercus alba L.) but later determined to be a bur oak hybrid (bur oak). We chose these late dates because this is the time when leaves would most likely be harvested for forage or found on the ground and consumed by cattle. Samples were selected randomly from many locations on the tree and combined. Two or more trees were sampled from each species except for Osage orange and cottonwood, where only one tree of each was sampled. Leaf samples from each species were collected from the ground (if present) directly below the sampled trees at the same time trees were sampled. The length of time they may have been on the ground was not known, although they were current year's leaves. After collection, all leaves were dried in a forced-air dryer (60°C), ground through a 1-mm mesh screen, and stored in sealed containers for analyses.

Micro-kjeldahl nitrogen (N) was determined colorimetrically and crude protein estimated by N × 6.25. In vitro matter disappearance (IVDMD) was determined via the NC-64 two-stage direct acidification method (Marten and Barnes 1980). Tannic acid equivalents (TAE) were determined by the Folin-Denis method (Burns 1963) using a 4-hour extraction period and are reported on a dry matter basis. Experimental design was completely randomized. Data were analyzed by analysis of variance. Crude protein, IVDMD and TAE least squares means were separated at P < .05.
Youdens' method (1967) was used to rank the trees for forage quality.

Results and Discussions

Crude Protein Content

Overall mean leaf crude protein in our study declined (Table 1) with time. Others (Bissell and Strong 1955, Hagan 1953, Tew 1970) have reported declining protein levels; however, McLeod (1973) showed a significant seasonal effect in only 1 species of 7 in Australia. Withdrawal of protein from leaves to the branches shortly before leaf abscission may explain the leaf protein decline.

Leaves on the tree compare favorably in crude protein content with Flint Hills True Prairie vegetation. Understory vegetation samples taken over the same 2-year period averaged 4.7, 3.9, and 2.5% crude protein during mid September, early October, and late October, respectively (Forwood 1982). That is considerably lower than the 2-year intact leaf average over all tree species of 10.6, 10.2, and 7.4% crude protein for similar dates (Table 1). That cattle may select recently fallen tree leaves over True Prairie understory vegetation is not surprising as protein content of the latter often falls below the subsistence level required by cattle about mid-July (Rao et al. 1973). The crude protein content of fallen tree leaves (Fig. 1) remains practically the same if not greater (3.7%) than understory vegetation in early or late October (3.9 and 2.5%, respectively). We found fallen leaves to contain significantly lower crude protein than leaves on the tree (Fig. 1). Sampson and Samisch (1935) reported similar results.

Digestibility

Significant differences were found among main effects for date and species (Table 2). Means over all species show the first and last sample dates were not different, although digestibility increased during the 2 intermediate sample dates. A similar trend has been documented in other trees and, like our study, some species show no differences between sample date (McLeod 1973).

Means over all dates showed significant differences in the digestibility of the species studied (Table 2). The range of species means over all dates in our study was between 42.6 to 73.1%. Others have shown digestibility of tree foliage in the 40–60% range (Oldemeyer et al. 1977, Joshi and Ludri 1966, Mia et al. 1960, Wilson 1977). Of

1Youden's method specifies that for this number of tests and species, species with point totals over 40 or under 20 are significantly superior and inferior, respectively, at the 5% level.

**Superior forage quality.

Osage orange clearly had highest quality forage in the group. Based on the analyses, Osage orange accumulated 59 of 60 possible ranking points. Although cottonwood ranked highly in IVDDM and TAE analyses, its low crude protein level resulted in a mediocre final quality ranking. Bur oak received the poorest quality ranking due to low digestibility and high TAE levels. Interestingly, the bur oak ranked significantly higher in forage quality than bur oak.

Browse eaten sparingly in feeding trials is sometimes observed to be eaten readily in the field (Wilson 1977). Single species are rarely eaten in the field as opposed to tests conducted in feeding or laboratory trials. In addition, components resulting in enhancement or inhibition of digestion may be accentuated in a single species test. Generally, however, leaves from these Flint Hills trees and from other areas are grazed by livestock in the presence of other available forages. This study indicates that leaves from these trees contain desirable quality components and at times may be of higher quality than True Prairie understory vegetation. Nutritional value of tree leaves is useful not only to those interested in browse for wildlife but also when severe drought conditions or

**Agricultural Research Service (ARS)**

**National Program Leader**

**Forage, Pasture, and Range**

Highly qualified scientist is needed to assume the duties of national program leader and will serve as the focal point for national leadership and coordination of agricultural research programs relating to forage pasture, and rangelands on the Agricultural Research Service’s National Program Staff.

The successful candidate will focus on building broad multi-disciplinary research programs to solve national agricultural problems conducted throughout the United States and in several foreign countries. Candidates must demonstrate skills for program planning, setting research priorities, allocating resources, and evaluating programs.

**Qualifications:**

In addition to the minimum educational requirements, candidates must have 3 years' professional experience in the programs related to forage, pasture, and rangelands. Some education may be substituted for a portion of the experience requirements.

The position is located in Beltsville, Maryland. Grade level is GM-15. Salary range is $50,495 to $65,642, based on qualifications and experience. U.S. citizenship is required. Candidates must contact the person listed below to obtain an application package.

Applications must be received no later than February 28, 1985 and sent directly to:
